Abstract: *Astrocaryum jauari* Mart. (Arecaceae) is one of the commonest palm species occurring in nutritionally poor Amazonian black water floodplains. It is an emergent or subcanopy tree that grows on river banks and islands, with a wide distribution along the entire flooding gradient, tolerating flood durations between 30 and 340 days. The species is important for fish nutrition in the floodplains, and is also used for hearts of palm. In the present study, the auto-ecology of *A. jauari* was analysed over a period of two years in the Anavilhanas Archipelago, Rio Negro, Brazil, with a focus on phenology, fruit production, and seed dispersal. Fruit fall is annual and synchronized with high water levels, with a production of 1.6 ton of fruit ha⁻¹. The fruits are eaten by at least 16 species of fish which either gnaw the pulp, fragment the seed, or ingest the entire fruit, thus acting as dispersal agents. Besides ichthyocory, barochory (with subsequent vegetative propagation) is an important dispersal mode, enhancing the occurrence of large masses of individuals in the Anavilhanas islands and in the region of maximum palm heart extraction near Barcelos. Rev. Biol. Trop. 54 (4): 1171-1178. Epub 2006 Dec. 15.

Key words: *Astrocaryum jauari*, floodplains, Amazonia, Anavilhanas, Brazil, ichthyocory, barochory.

Floodplain forests of large rivers in the Amazon region are subjected to water level fluctuations of about 10 m every year, as the result of the sum of the precipitation in the catchment area (Goulding 1983). The regular annual occurrence of an aquatic and a terrestrial phase is of high ecological importance (Junk *et al.* 1989) and led to the evolution of a specific vegetation (Kubitzki 1989, Prance 1979) highly adapted to survive partially or totally submerged periods of up to 210 days, depending on the position of the individuals in the flooding gradient (Junk 1993).

According to the water properties of the related rivers and the flora, two major floodplain ecosystems can be distinguished, the nutritionally rich „várzea“ associated to white water rivers like the Amazon, and the nutritionally poor „igapós“, associated to black water rivers like the Rio Negro (Sioli 1975,

Prance 1980). Owing to the high acidity, mineral content and low light penetration in the igapós, aquatic herbaceous vegetation (Junk and Piedade 1997) and phytoplankton production (Sioli 1976, Schmidt 1973) are very poor. Life in this ecosystem therefore strongly depends on the allochthonous primary production of the riparian forests (Erwin and Adis 1982, Junk *et al.* 1989, Junk and Piedade 1997).

In flooded forests, several plants dispersed by animals developed hard pericarps to protect the seeds against the acids of their digestive apparatus (Cronquist 1974). In such environments, the sound of fruit falling into the water can attract dispersors like fish (Van der Pijl 1969), particularly if the fruits are heavy like those of palm trees. One of these, *Astrocaryum jauari* Mart. (Fig. 1A, B), which is frequent in the black water floodplains of the Rio Negro and its affluents, produces fruits which

are consumed by fish (Fig. 1C; Gottsberger 1978, Goulding 1980, 1983). The commercially important Characidae family, and especially two of the most important fish in terms of local consumption and exportation, *Colossoma bidens* (pirapitinga) and *Colossoma macropomum* (tambaquí), feed on *A. jauari* and disperse its seeds (Goulding 1980). However, the fish may act also as predators, since they possess strong mandibles able to triturate the hard seeds.

Also the species' exploitation by man is considerable. The traditional use by indigenous people has been documented: *A. jauari* provides fiber, food, and shelter (Gragson 1992). In Puerto Ayacucho in the State of Amazonas, Venezuela, at least four indigenous groups (Piaroa, Curripaco, Guahibo and Baniva) from ten neighboring communities, include palm products in the economic support of their families (Narvaez and Stauffer 1999). Owing to the high quality and tenderness of the hearts of palm, this species was exploited for more than 20 years, supplying all hearts of palm commercialized in Central Amazonia between 1978 and 1998 (Piedade 1985, Piedade *et al.* 2003) before being replaced by *Bactris gasipaes* from plantations (Alírio Rocha, pers. comm. SHARP S/A).

Although the species is common and of high ecological importance, information about the vegetative and reproductive phenologies, and their timing with respect to the flood pulse, is completely missing. Dispersal mechanisms and their relationship with the local distribution and population structure as well as the contribution of fruits to the food chains are analyzed in the present study.

MATERIALS AND METHODS

Study sites: Data on phenology and on fruit production were collected in the

Anavilhanas Archipelago, Rio Negro, Central Amazon, at the Anavilhanas Ecological Floating Station (AEFE) of the Brazilian Institute of Environment (Instituto Brasileiro de Meio Ambiente - IBAMA), about 100 km from the city of Manaus (between 2°00' and 3°02' S of latitude and 60° 27' to 61°07' W of longitude).

The main period of data collection was from August 1980 to November 1982. From this year to 1998 irregular field trips added occasional observations, and data about the commercial extraction of the palm tree were collected.

Climate: The climate is hot and humid with mean minimum temperatures above 18 °C (Ribeiro 1976). The most arid month (October) has a relative humidity above 60 %. Mean annual precipitation ranges between 1 000 and 2 500 mm (Fig. 2; Irmiler 1975). Annual river level fluctuations in the Anavilhanas Archipelago show a similar pattern and amplitudes like those measured at the harbour in Manaus, with an annual mean amplitude of 10 m (Fig. 2; Schmidt 1973).

Vegetation: In the study sites, the vegetation forms three strata and has low plant densities. The taller trees reach 15 to 20 m height, with some emergent individuals about 25 m high (Piedade 1985). During high water levels, the vegetation is partially or totally inundated.

Fig. 2. Reproductive phenology of *A. jauari* in the study site near the Anavilhanas Ecological Floating Station (AEFE) in the Anavilhanas Archipelago, Rio Negro, Central Amazonia, with river level and precipitation. Young fruits are defined as green, less than 3 cm wide; mature fruits as yellowish.

RESULTS

Medium height of mature *A. jauari* is 20 m, with dense tree crowns, which have 6 to 14 leaves (Boer 1965), each one with a mean length of 3 m. *A. jauari* may occur isolated but more frequently the species forms huge stands along the margins of rivers or lakes (Corrêa 1969, Goulding 1980). The species may form clones with 4 to 6 individuals differing in size but belonging to a single rhizome (Boer 1965).

Phenology and fruit production: Nine healthy, adult individuals of *A. jauari* were marked and the phenological status was recorded once a month. Presence or absence of flowers, young and mature fruits were recorded as well as fruit maturation time. In the period of fruit maturation, phenology was recorded at weekly intervals. Ten fruit bunches were collected from different individual trees, to ascertain total number of produced fruits and fruit weight and size. Twenty fruits per bunch were weighed. Additionally, 250 seeds were collected from different bunches for chemical analyses which were performed in the INPA, Manaus. Water content (in percent, after oven drying at 80 °C to constant weight), and the contents of protein, fat, ash, carbohydrates, calories and vitamin A were measured.

Dispersal: Dispersal syndromes were observed on the marked trees. To estimate predation, fruits were monitored for ten weeks as follows: 1 000 fruits were collected from the bunches (pre-dispersal predation), and 3 000 fruits were collected from the soil (post-dispersal predation). In order to establish the efficiency of water as a dispersal agent, 1 000 seeds were collected floating at the water surface and opened to analyse the embryonal integrity. Systematical analyses of fish stomach content were performed at the Ecological Station. To this information were added bibliographical data and interviews with local people.

Exploitation: Data on palm extractivism until 1998 were gained from the technicians of the Fábrica de Palmito Jauari, SHARP do Brasil S.A., Manaus/AM.

Phenology and fruit production: The production of flowers and fruits of *A. jauari* occurs once every year. The great majority of the adult palms starts the production of flowers when the water of the rivers are sinking and precipitation is not very intense yet, especially in August and September (Fig. 2). The flowering period is short and is soon substituted by the presence of small fruits which develop slowly. The fruits are mature when the river levels rise again, after about nine months, with abscission occurring mainly at high water levels in the months May to July (Fig. 2). No pre-dispersal predation was detected.

Every individual of *A. jauari* produces four fruit bunches every year, which are 90 cm long on average and have a mean fruit number of 106, with a mean weight per fruit of 17 g (Table 1).

The chemical analyses of fruits of *A. jauari* (Table 2) show that the pulp and the seed consist mainly of water and carbohydrates, with a high percentage of fat (14.7 %) in the seed.

Dispersal: Since mean fruit weight is high (Table 1), and morphological features enhancing flotation are completely lacking, the fruits sink to the bottom when they fall into water. If fruits were found floating, then the seeds were not viable and all deteriorated. As a consequence of topographical conditions, after abscission the fruits may fall and be accumulated close to the mother plant (barochoric dispersal, Fig. 3). Under such conditions, some of the seeds may be predated by small coleoptera. They may also roll away from the mother plant, in many cases aided by the action of water. The fruits found in these conditions are less in number, and are located in isolated points on the islands. Ichthyochoric dispersal plays a major role: a total of 16 fish species feed on the fruits of *A. jauari* (Table 3). These belong to five families, mainly to the Characidae. Ten of the 16 species were categorized as possible dispersers, although three (*C. macropomum*, *C. bidens* and *Prachtocephalus hemiliop-*

terus) may also act as predators since they do not only swallow the whole fruits, but sometimes chew and destroy them with their strong mandibles and teeth (Goulding 1980).

This could not be measured and quantified in the present study. In the whole study period, we did not observe any indications of other vertebrates feeding on fruits of *A. jauari*.

Fig. 3. Dispersal mechanisms of *A. jauari*. Schematic presentation with high and low water levels in a year of short flood duration.

Exploitation: Regarding the economic exploitation of *A. jauari*, the information provided by the Fábrica de Palmito Jauari-SHARP do Brasil S.A. indicate that in the region of the Municipality of Barcelos where the extractivism occurs, the density of the palms varies widely between river islands, from 250 to 2 000 individuals/ha. One single worker can fell and pre-clean up to 90 palm trees

At high water (May to July) (data from Goulding 1980, 1983 from stomach content fish analyses performed at the Anavilhanas Ecological Station, from interviews with local people, and from G. Borges and M.C.L.B. Ribeiro, pers. comm.). xxx high, xx mean, x low frequency.

in the high water season in the months of May to June and about 25 in the low-water season (December, January). Calculating a number of ten workers in the area of Barcelos, 250 to 900 palms are exploited every day, corresponding to 0.5-1 ha. From one palm 0.5-1 bin of hearts of palm may be obtained. From October 1998 on, due to difficulties in keeping up a constant production, hearts of palm production of the SHARP S.A. was completely substituted by the palm *B. gasipaes* H.B.K (pupunha) which were planted on a 45 ha area with a total of 225 000 palm trees.

DISCUSSION

The distribution of *A. jauari* was quite variable among different islands, occurring on sites flooded for 270 to 340 days per year on one island, while on an adjacent island

they dominated in areas flooded for 30 to 200 days per year. This high amplitude of distribution was already pointed out by Huber (1906) for populations of *A. jauari* along the Rio Purus. It is possible because the palm is well-adapted anatomically and physiologically to hypoxic conditions (Schlüter *et al.* 1993). Annual inundation for as long as 300 days, at water temperatures of 28 °C, produce neither leaf loss nor rotting of the roots. Well-developed aerenchyma permits gas transport from the branches to the roots. At a depth of 1.2 m beneath black waters, the leaves in the crowns of the plants show little decrease in the amount of chlorophyll.

Phenological patterns between sites are quite similar. *A. jauari* synchronizes its flowering with the period in which precipitation is less intense. With the onset of high precipitations, the fruits are growing already - a process which may last nine months- and at highest

water levels the abscission of mature fruits is at its maximum. Perhaps this long period of maturation is necessary to reach the high energetic and vitaminic level of the fruits (Table 2), since the soils of the black water floodplains are extremely poor in nutrients (Sioli 1976). The long maturation phase is also necessary for the synchronization of fruit production with high water levels and the related seed dispersal by fish. The high nutritional value of the fruits (Table 2) may be related to the ichthyochoric dispersal syndrome. The especially high content of vitamin A may be advantageous for fish to put up stock reserves in the form of fat which are needed for gonads development in the low water period when food resources are scarce. Goulding (1980) found 52 entire fruits of *A. jauari* in only one individual of *C. macropomum*, and in one individual of *C. bidens* he found 1 kg of *A. jauari* fruits. The noise of fruits falling into the water attracts fish and thus contributes to the success of the propagation mechanism.

All floating fruits were no longer viable, indicating that hydrochory does not play a role in *A. jauari*. Although Corner (1966) emphasizes that in the genus *Astrocaryum* dispersal by flotation is frequent and apparent, in the case of *A. jauari* the heavy fruits may eventually be transported submerged by currents, but definitely not by flotation.

The observed local increases of population density probably result from barochory, and from vegetative propagation which enhances the occurrence of large masses of individuals in the Anavilhanas islands, and of even higher densities in the region of maximum extractivism, near Barcelos.

Hydrochory is probably of neglectable importance, and ichthyochory is responsible for long distance dispersal helping to colonize new habitats. Van der Pijl (1969) states that ichthyochory is a primitive dispersal mechanism which in floodplains of Amazonia and Borneo has been maintained in ancient plant groups. These primitive mechanisms of dispersal usually imply a huge production and loss of fruits, since these mechanisms are highly

hazardous in terms of the possibility of finding an appropriate place for germination, and they allow several opportunists to exploit the resource (Janzen 1970 1971, Fleming and Heithaus 1981).

Finally both, the intensive extraction of the palm, and the pressure over the populations of the most probable fish acting as dispersors may lead to the impoverishment of food chains in black water Amazonian floodplains, and to the decline of densities of *A. jauari* and some of the economically important fish species.

RESUMEN

Astrocaryum jauari Mart. (Arecaceae) es una de las especies más comunes de palma en las llanuras de inundación por las llamadas "aguas negras", aguas ricas en taninos que tienen pocos nutrientes para la fauna. Habita el subdosel que se desarrolla en riberas e islas, con una distribución amplia en toda la gradiente de inundación (resiste entre 30 y 340 días bajo el agua). La especie es importante para la nutrición de los peces y en la producción de palmito. La autoecología de *A. jauari* fue analizada por dos años en el Archipiélago Anavilhanas, río Negro, Brazil, con énfasis en fenología, producción de frutas, y dispersores de semillas. La caída de los frutos es anual y sincronizada con el aumento de los niveles de agua, con una producción de 1.6 ton de fruta ha⁻¹. Las frutas son comidas por al menos de 16 especies de peces que roen la pulpa o fragmentos de semilla, o ingieren la fruta entera y actúan como agentes dispersores. Además de la ictiocoria, la barocoria y la subsecuente progargación asexual son básicos para la alta densidad de la especie.

Palabras clave: *Astrocaryum jauari*, llanura de inundación, Amazonía, Anavilhanas, Brasil, ictiocoria, barocoria.
